Guidelines For
Preliminary Design Of
Bridges And Culverts

Appendix C

Scour

Introduction

The most common cause of bridge failures in the nation is flooding, with bridge scour being the most common type of flood damage. Bridge scour is a complicated process and provides challenges to engineering analysis. Because of public safety and high replacement and repair costs, the need exists to evaluate or improve current design and maintenance practices concerning bridge foundations.

The objective in this appendix is to detail three items:

1. Factors that affect scour.
2. Recommendations to reduce or prevent scour effects on existing and proposed bridges.
3. Methods to estimate scour for existing and proposed structures.

Definition

A basic definition of scour is the result of erosive action of moving water as it excavates and carries away material from a streambed and banks. There are two types of scour:

1. General scour - the loss of material from most or all the bed and banks, usually caused by the road embankment encroaching onto the flood plain with resulting contraction of the flood flow (often called contraction scour).
2. Local scour – the loss of material around piers, abutments, spur dikes and embankments.

There are two conditions for contraction and local scour: clear-water and live-bed. Clear-water scour occurs when there is little to no movement of the bed material of the stream upstream of the crossing. Typical situations include most overflow bridges, coarse bed material streams, and flat gradient streams during low flow. Live-bed scour occurs when velocities are high enough to move the bed material upstream of the crossing. Most Iowa streams and rivers experience live-bed scour.

Streambed degradation, such as in the Western Iowa loess region, is considered in some documents to be scour. Even though degradation can affect structural stability like local or general scour does, the causes of degradation are of a different nature, and it will not be discussed in detail in this document.

The effects of scour are a complex problem involving geotechnical, hydraulic, and structural concerns, so decisions concerning scour should involve engineers in each of these disciplines.

Design guidelines and considerations

Numerous factors affect the stability of the bed and banks of a stream and are discussed below with some guidelines and considerations.

1. Soils

Soils with any combination of sand or silt have greater potential for scour: sand, silt, sandy silt, sandy silty clay, etc. As a general rule, according to IDOT's Soils Design Section, soils which have a blow count of ten or less are particularly susceptible.

Excessive loss of pile bearing due to scour is one cause for bridge damage or failure. However, perhaps a more common cause of failure is soil instability associated with the road embankment and bridge berm. Often a bridge berm or fill behind a high abutment has minimal factor of safety for stability. If this safety factor is reduced due to scour at the toe of the embankment, the soil may become unstable resulting in a slip failure. Damage to an abutment, pier or approach fill is a possible outcome.

For replacement structures, designing flatter berm slopes and/or placing the abutments farther from the channel will provide a greater safety factor. Then, when scour does occur, the embankment will more likely remain stable. For existing structures, protection of the berm, especially the toe, may be necessary.

2. Substructure

Generally, wider and longer piers have greater scour potential. Deeper footings and longer piles are more stable at greater scour depths. Spread footings should be used only on material highly resistant to scour such as limestone and some shales.

To maintain the integrity of the structure, do not allow scour to reduce pile bearing below a desirable safety factor that is selected by the structural or geotechnical engineer. Designing for this minimum safety factor may require designing longer piles for new bridges. For existing structures, protection of the piles may be necessary to maintain the safety factor.

New bridges should have sufficient length so that the abutments do not encroach on the channel but placed as far back from the streambank as practical. Vertical wall abutments (high abutments) have a greater potential for general and local scour as compared to the spillthrough type (integral or stub abutments).

3. Flood discharge

In the publication "Evaluating Scour at Bridges", Hydraulic Engineering Circular No. 18 (HEC-18), the FHWA recommends using a Q_{100} or lesser discharge for scour analysis, depending on which results in the most severe scour conditions. Usually the overtopping flood results in the

worst scour, so check this flood (if less than the Q_{100}) and the Q_{100}.

The discharge used in scour design is generally larger than that used in hydraulic design. For example, hydraulic design guidelines for a bridge may be a Q_{25} discharge, but the scour design may use a Q_{100}. The rationale for this is that hydraulic design involves backwater and ensures that the bridge size will be adequate under normal flood conditions. In scour design, a higher discharge is used to ensure that the bridge will remain stable and will not fail or suffer severe damage during extreme flood events.

FHWA also recommends checking scour conditions for a superflood, such as a Q_{500}. If Q_{500} data is not available, HEC-18 recommends using 1.7 X Q_{100}. The safety factors for the bridge should remain above 1.0 under this flood condition. Similar to that mentioned above, $Q_{overtopping}$ may be the worst-case flood and should be used if it is less than Q_{500}.

4. Interaction between road and flood plain

A highly skewed river crossing provides a less hydraulically efficient bridge opening and therefore has a greater contraction scour potential. Also, a high ratio of overbank flow to main channel flow will result in a greater contraction scour potential. For these situations, scour can be reduced by using wing dikes and/or riprap.

Road grade overflow or overflow structures may provide relief and reduce scour potential for the main channel bridge.

5. Interaction between piers and flood flow

The width, length and type of pier (e.g., pile bents, "tee" piers) all have an effect on local scour. Closely spaced piles in a pile bent pier can act similar to a solid wall. The angle of attack of flood flow to the pier can also significantly increase scour if this angle changes due to channel meandering during the life of the bridge. For example, if the angle of attack changes from 0° to 15°, the pier scour approximately doubles. The stream's history of and future potential for meandering should be examined.

6. Debris and ice

Visual observation can be made and maintenance records can be checked to determine the history of debris and ice on the stream. Debris and ice can snag on the piers or superstructure, placing additional stresses on the bridge as well as promoting local scour. This scour can sometimes be quite significant although difficult to estimate. Therefore, for new designs, give consideration to raising the low superstructure above the low roadgrade elevation. This will allow hydraulic relief if the bridge opening becomes clogged.

Estimating scour

Procedures for estimating scour have been researched in the past 40 years in an attempt to develop reliable prediction equations. Some of these equations give reliable results, others do not. The Federal Highway Administration has attempted to find the best equations and published them in HEC-18.

HEC-18 contains equations for contraction scour, abutment scour and pier scour. The contraction scour equations are the best available equations of their type and sometimes provide reliable estimates, although these estimates still need to be evaluated considering soil types, site scour history, etc. The abutment scour equations frequently give questionable estimates. Because of comments similar to this from various states, FHWA is conducting additional research to develop new methods. At this time, IDOT recommends not using FHWA's abutment scour equations or, at most, use them with caution. However, be aware that abutment scour can occur.

Concerning pier scour, the equation in HEC-18 generally gives reliable results. However, a much simpler method that gives very similar results is found in Iowa Highway Research Board's Bulletin No. 4, "Scour Around Bridge Piers and Abutments," by Emmett M. Laursen and Arthur Toch, May 1956. This method for estimating pier scour can be used in most cases instead of the methods in HEC-18.

1. Contraction scour estimation

See Chapter 4 of HEC-18 for detailed instructions on how to calculate contraction scour. To help explain this chapter, there are two determinations that must be made when estimating contraction scour:
- The appropriate case of contraction scour that depends on the flow interaction of the bridge to the channel and floodplain. There are four of these cases. See the figures later in this document for graphical illustrations of these cases.
- The appropriate sediment transport condition. There are two of these conditions and equations (live-bed and clear-water) that can occur in any of the four cases mentioned above.

Both determinations are explained below.

Four cases of contraction scour
Case 1 is overbank flow being forced back into the main channel due to the road fill. The majority of bridges in Iowa will be Case 1. There are three variations to Case 1, depending on the location of the abutments or abutment berms compared to the channel:

> **Case 1a** is normally used when the river channel width becomes narrower due to the bridge abutments (or berms) projecting into the channel.

> **Case 1b** does not involve any contraction of the channel itself, but the overbank flow area is completely obstructed by the embankment. In other words, the abutments or abutment berms are on the channel bank.

Case 1c is when the abutments or abutment berms are set back from the channel. This case is more complex because there is both main channel flow and overbank flow in the bridge opening. Therefore, refer to discussion in Section 4.3.4 of HEC-18. More hydraulic analysis may be needed than in Cases 1a and 1b (such as WSPRO) to determine the distribution of flow in the bridge opening, i.e., what is the discharge in the main channel (Q_2) and the discharge in the overbank under the bridge ($Q_{overbank2}$).

Most Case 1 streams in Iowa will have live-bed scour. However, if the streambed material has particles larger than a sand classification, calculate V_c (see below) to determine if clear-water scour will occur instead of live-bed scour.

Case 2 is when the stream has no overbank flow. This case will be common in Western Iowa streams that are severely degraded.

Case 3 is an overflow (relief) bridge with no bed material transport, so use the clear-water scour equations. Hydraulic analysis (e.g., using WSPRO) is needed to determine the flood plain width associated with the relief opening and to determine the total flow going through the relief bridge.

Case 4 is an overflow (relief) bridge similar to Case 3 except it <u>does</u> have sediment transport (live-bed scour), such as over a secondary channel on the flood plain of a larger stream. Hydraulically this case is no different than Case 1 except that analysis (e.g., using WSPRO) is needed to determine the flood plain width associated with the relief opening and the portion of the total flow going through the relief bridge.

Sediment transport conditions: Live-bed scour versus clear-water scour
Before an equation is selected to estimate contraction scour, it is necessary to determine if the flow is transporting bed material. If it is, the flow will create live-bed scour. If it is not, the flow will create clear-water scour. There are different scour equations for each of these sediment transport conditions.

Most Iowa stream channels will be live-bed. In other words, the velocities in the channel will be high enough to cause movement of the soil particles in the streambed. In order to be sure if the channel is live-bed, Chapter 2 in HEC-18 gives a simple equation to calculate the velocity needed to cause movement of the soil:

$$V_c = 10.95 \, y^{0.167} \, (D_{50})^{0.33}$$

where V_c = critical velocity which will transport bed materials of size D_{50} and smaller, ft/sec.
         y = depth of upstream flow, feet
         D_{50} = median diameter of the bed material, feet

If the velocity in the channel is greater than V_c, then the particles will move and the stream will have live-bed scour. If the velocity in the channel is less than V_c, then the particles will <u>not</u> move and the stream will have clear-water scour.

Most Iowa streambeds have sand or silt which results in a very low V_c. This means that even a low flood velocity will move the particles. Therefore, most Iowa streams will have live-bed scour. For example, for a medium sand with a D_{50} of 0.0012 feet (0.375 mm) and a flow depth of 12 feet, V_c is 1.8 ft/sec. Any flood with a channel velocity higher than this will cause sediment transport and therefore create live-bed scour. Even a medium gravel streambed with D_{50} of 0.039 feet (12 mm) and depth of 12 feet results in V_c of 5.7 ft/sec. Again, most Iowa streams will have a channel velocity higher than this.

In summary, as a rule of thumb, if the streambed material is larger than sand, calculate V_c and compare to expected channel velocities to determine if live-bed or clear-water scour occurs. If the material is sand or smaller, assume live-bed scour occurs.

Live-bed scour
From HEC-18, the equation for live-bed scour is as follows:

$$\frac{y_2}{y_1} = \left[\frac{Q_2}{Q_1}\right]^{0.86} \left[\frac{W_1}{W_2}\right]^{k1}$$

and $y_s = y_2 - y_1 =$ average scour depth, ft

where y_1 = average depth in the upstream main channel, ft
   y_2 = average depth in the contracted section (i.e., in the bridge opening), ft
   W_1 = top width of water in the upstream main channel, ft
   W_2 = top width of water in the main channel in the contracted section (i.e., in the bridge opening), ft
   Q_1 = discharge in the upstream main channel transporting sediment, cfs.
      (Q_1 does not include upstream overbank flow)
   Q_2 = discharge in the contracted channel (i.e., bridge opening), cfs
      (For Cases 1a and 1b, Q_2 may be the total flow going through the bridge opening. For Case 1c, Q_2 is <u>not</u> the total flow through the bridge since there is also some overbank Q adjacent to the channel under the bridge.)
   k_1 =   exponent. Assume $k_1 = 0.64$ to simplify the calculations since the range for k_1 in HEC-18 Section 4.3.4 makes very little difference on calculated scour depths.

This results in the live-bed scour equation of:

$$\frac{y_2}{y_1} = \left[\frac{Q_2}{Q_1}\right]^{0.86} \left[\frac{W_1}{W_2}\right]^{0.64}$$

Simply stated, the ratio W_1/W_2 reflects contraction or expansion in the channel. The ratio Q_2/Q_1 reflects the effect of forcing overbank flow through the bridge opening.

This equation is generally used for Case 1 (when streambed consists of sand-size particles or smaller) and Cases 2 and 4. In Case 1c, the live-bed scour equation is used for the main channel contraction scour and the clear-water scour equation is used for the contraction scour near the abutment on the overbank.

Clear-water scour

From HEC-18, the equation for clear-water scour is as follows:

$$y_2 = \left[\frac{Q^2}{139\,(D_{50})^{0.67}\,(W_2)^2} \right]^{0.43}$$

and $\quad y_s = y_2 - y_1$ = average scour depth, feet

where $\quad y_2$ = depth in the bridge opening, ft

Q = discharge through the bridge opening or on the overbank portion of the bridge opening, cfs

D_{50} = median diameter of material in overbank, feet (see attached sediment size table from HEC-20)

W_2 = top width of water in bridge opening or overbank width in bridge opening (set-back distance), feet

y_1 = upstream depth, ft

The average depths y_1 and y_2 are measured either in the channel for channel scour calculations or on the overbank for overbank/abutment-area scour calculations.

The clear-water scour equation is used for a few Case 1 bridges (when streambed particles are larger and, in Case 1c, when the abutment is set back a distance from the channel) and for all Case 3 bridges.

Summary of estimating contraction scour
- Determine which "case" is appropriate
- Determine if the channel has live-bed or clear-water scour
- Analyze the hydraulics
- Using the correct equation, estimate scour
- Evaluate the reasonableness of estimated scour

2. Abutment scour estimation

The equation given in Section 4.3.6 of HEC-18 is for the worst-case conditions. The equation will predict the maximum scour that could occur for an abutment projecting into a stream with velocities and depths upstream of the abutment similar to those in the main channel. In most cases, the equation will over-predict scour, especially the farther the abutment is from the channel. Do not calculate abutment scour at this time due to this questionable equation. Be aware, however, that scour at the abutments can occur. Site experience is very important in the engineering analysis, including known scour occurrences and settlement of approach pavement which indicates soil stability problems. It is important to note that high abutments may have up to twice the scour depths as spillthrough abutments.

A conservative approach in determining effects of scour on the abutments is to assume that contraction scour is added to abutment scour when the abutment is near the channel.

Several questions should be considered for abutment stability. Is the soil scourable? What is the effect on berm stability? Are flatter berm slopes or a longer bridge needed? What is the effect on pile bearing? Are longer piles needed? Should riprap or wing dikes be used?

3. Pier scour estimation

Use "Scour Around Bridge Piers and Abutments", Emmett M. Laursen and Arthur Toch, Iowa Highway Research Board, Bulletin No. 4, 1956, for most cases.

Figure 39 in Bulletin No. 4 is the basic design curve for pier scour. IDOT determined an equation from this curve:

$$\left(\frac{y'_s}{w_p}\right) = 1.485\left(\frac{y_1}{w_p}\right)^{0.314} \qquad\qquad \text{Equation 1}$$

where
  y'_s, unfactored depth of scour, ft
  y_1, unscoured depth of flow, ft
  w_p, width of pier column, ft

Equation 1 is then substituted into the basic equation, resulting in Equation 2 below:

$$y_s = (K)\ (y'_s) = (K)\ (w_p)\left(\frac{y'_s}{w_p}\right)$$

$$y_s = 1.485\ (K)\ (w_p)\left(\frac{y_1}{w_p}\right)^{0.314} \qquad\qquad \text{Equation 2}$$
  where y_s is depth of scour, ft
   K, a pier coefficient (either K_a or K_s),
    K_s, coefficient for pier nose shape (see below). Use only if angle of attack = 0.
    K_a, coefficient for angle of attack if angle is not zero (see table below).

Equation 2 should be used to calculate pier scour.

C8

If angle of attack <u>is</u> zero, use one of the following values for K_s , the coefficient for the shape of the upstream nose of the pier (adapted from Bulletin No. 4). Use this K_s value in Equation 2 in place of K. These values show that the better the "rounding" of the pier nose, the lower the pier scour.

		L	
Rectangular	1.0	▭	w_p
Semicircular	0.9	◁▭	w_p
Elliptic	0.8	◁▭	w_p

If angle of attack is <u>not</u> zero, use the following table adapted from Figure 39 in Bulletin No. 4 to determine K_a. In this table, L = length of pier, and w_p = width of pier. Use this K_a value in Equation 2 in place of K. The values in the table show that as the angle of attack increases, the pier scour increases dramatically. For example, for a pier L/ w_p of 8, if the angle of attack changes from 0° to 15°, the factor K_a changes from 1.0 to 2.0, doubling the calculated pier scour.

Design Factors (K_a) for Piers Not Aligned With Flow

L/w_p Angle of Attack	4	6	8	10	12	14
0°	1.0	1.0	1.0	1.0	1.0	1.0
5°	1.2	1.3	1.3	1.5	1.6	1.6
10°	1.4	1.5	1.7	1.9	2.1	2.3
15°	1.5	1.8	2.0	2.2	2.5	2.7
20°	1.7	2.0	2.3	2.5	2.8	3.0
25°	1.8	2.2	2.5	2.8	3.1	3.5
30°	1.9	2.4	2.7	3.1	3.4	3.8
35°	2.0	2.5	2.9	3.3	3.7	4.0
40°	2.1	2.7	3.1	3.6	4.0	4.3
45°	2.2	2.8	3.3	3.8	4.2	4.6

See Scour Calculation Sheet to assist in pier scour estimation. Other subjects concerning pier scour discussed in more detail are found in Section 4.3.5 of HEC-18:
- Pier scour for exposed footings and exposed pile groups under a footing
- Pier footings that are above normal streambed
- Multiple columns in a pier (e.g., a pile bent pier)
- Pressure flow scour
- Scour from debris
- Width of pier scour holes

Summary of estimating pier scour:

- Analyze hydraulics
- Estimate scour
- Evaluate the reasonableness of the estimated scour
- Add pier scour to contraction scour to obtain total scour
- Determine action steps such as countermeasures or design features of the bridge

Coding for the Structure Inventory and Appraisal (SI&A)

See the attached pages from FHWA's "Recording and Coding Guide for the Structure Inventory and Appraisal of the Nation's Bridges" to determine what rating should be given to each bridge. All countermeasures (SI&A Item 113 coded as "7") should be monitored in future years by bridge inspectors.

Countermeasures: reducing the effects of scour

Generally, a new bridge should be designed to withstand scour without countermeasures, especially when the countermeasures cannot be easily inspected. For example, riprap protecting a pier in the channel is difficult to inspect, but a wing dike in the overbank is easily inspected and repaired. Countermeasures will be used most commonly on existing bridges that are scour critical. See HEC-18, Chapter 7, for an in-depth discussion of when and how to use countermeasures.

In summary, listed below are common considerations to reduce scour on the bridges. Some items may be relevant only to existing bridges; others may be relevant only in the design phase of a structure.
- Use longer piles.
- Set the pier or abutment footings lower. However, lengthening piles is generally preferred due to lesser cost.
- Place riprap around the pier, abutment, berm slope, or spur dike or across the entire streambed. Riprap is an easy and often inexpensive way to protect a bridge.
- Build abutments as far from the streambank as possible.
- Remove debris from piers.
- Wing dikes (a.k.a., spur dikes, guide banks) provide for a more hydraulically efficient bridge opening and force the scour to occur on the dike, which is expendable, rather than on the bridge itself.

More expensive solutions can be considered in some instances:
- Place sheet piling to protect existing piers or abutments.
- Underpin the foundation.
- Replace with a new bridge.
- Construct an additional span.
- Overflow (relief) bridges can be used on flood plains that have substantial overbank flow. This provides relief for the main channel bridge. However, be aware that these overflow structures are particularly susceptible to deep scour. Twenty to thirty feet of scour is not

uncommon.

- Provide for roadgrade overflow which is a "relief valve" to the bridge opening during extreme flood events and can prevent or minimize damage to the bridge. A disadvantage to roadgrade overflow is potential hazard to the traveling public when water is over the road. These factors need to be weighed by the engineer when considering other factors such as traffic volumes, traffic speeds and costs.

Following are some design guidelines for sizing riprap and placing wing dikes as countermeasures. The recommendations concerning riprap are **not** intended to determine if it is needed, rather only how to properly size riprap.

1. Riprap at abutments.

Section 7.5.1 in HEC-18 gives several equations for sizing riprap at abutments. Considering these equations and past experience, IDOT recommends simplifying riprap design to the following:

When riprap is needed for countermeasure and the toe of the abutment berm or the vertical abutment is approximately 75 feet or less from the top of the bank, use the average velocity through the entire bridge opening to size the riprap. When the toe of the abutment berm or the vertical abutment is approximately 75 feet or more from the top of the streambank, use the average velocity in the overbank portion of the bridge opening.

When riprap is needed and the determined average velocity is less than approximately 8 feet per second, use IDOT's Class E riprap (D_{50} of 90 pounds). When the determined average velocity is greater than approximately 8 feet per second, use the Class B gradation which is heavier than Class E (D_{50} of 275 pounds.

2. Riprap at piers.

From Section 7.5.1 in HEC-18, , the equation for sizing riprap at piers reduces to the following (assuming specific gravity of 2.65 for riprap):

$$D_{50} = \frac{(K\,V)^2}{153.6}$$

where D_{50} = median stone diameter, feet
K = coefficient for pier shape (1.5 for round-nose pier, 1.7 for square-nose pier)
V = average velocity approaching pier, ft/sec

To determine V, multiply the average channel velocity (Q/A) by a coefficient that ranges from 0.9 for a pier near the bank in a straight uniform reach of the stream to 1.7 for a pier in the main current of flow around a bend.

The D_{50} for IDOT's Class E riprap is 90 pounds or approximately 1.0 foot diameter and will be adequate for many situations. From the above equation, this diameter will tolerate a velocity of 8.3 ft/sec for round-nose piers and 7.3 ft/sec for square-nose piers.

When the adjusted velocity exceeds this and riprap is needed as a countermeasure, consider using Class B riprap. This has a D_{50} of 275 pounds which is approximately 1.5 feet in diameter and will tolerate a velocity of approximately 10 ft/sec for round-nose piers and 9 ft/sec for square-nose piers. This gradation should be adequate in almost all situations where the standard gradation is not adequate.

According to HEC-18, the width of the riprap around the pier should at least twice the pier column width. However, on several countermeasure projects, IDOT has placed a much wider layer (25') around the entire pier. The riprap should be placed at or below the streambed so as not to create a greater obstruction to flow. HEC-18 recommends a thickness for the pier scour protection layer of 3 x D_{50} or greater. IDOT has used thicknesses of three and four feet on previous projects. Either guideline seems reasonable.

3. Wing dikes

Use IDOT Road Standard RL-3. Appendix B of "Guidelines for Preliminary Design of Bridges and Culverts" has a page to determine the length of wing dikes. See also HEC-20 or HDS No. 1 for further guidance.

W_2, top width of bridge opening or overbank width in bridge opening, ft	_____	_____
y_1, upstream depth, ft	_____	_____
$y_s = y_2 - y_1 =$ ave. scour depth, ft	_____	_____

Is this contraction scour depth realistic?
Is the soil scourable?
What is the effect on berm stability (including any abutment scour)?
Are longer abutment piles or a flatter abutment berm needed?
Should riprap or wing dikes be used?
Other comments?

PIER SCOUR

Use "Scour Around Bridge Piers and Abutments", Emmett M. Laursen and Arthur Toch, Iowa Highway Research Board Bulletin No. 4, 1956, for most cases. Use Equation 2 below and previous discussion in the text. Also, see Section 4.3.5 in HEC-18 for more discussion on estimating pier scour.

$$y_s = 1.485 \ (K) \ (w_p) \left(\frac{y_1}{w_p} \right)^{0.314} \qquad \text{Equation 2}$$

where y_s, depth of scour, ft
$\qquad$ y_1 , unscoured depth of flow, ft
$\qquad$ w_p, width of pier column, ft
$\qquad$ K, a pier coefficient (either K_s or K_a),
$\qquad$ K_s, coefficient for pier nose shape (see values in text). Use only if angle of attack = 0.
$\qquad$ K_a, coefficient for angle of attack if angle is not zero (see table in text).

	Q_{100}	Q_{500} or $Q_{overtopping}$
y_1, ft	_____	_____
w_p, ft	_____	_____
K (either K_a or K_s)	_____	_____
y_s, ft (from Equation 2)	_____	_____

TOTAL SCOUR AT PIER = pier scour (y_s) + contraction scour (y_s)

y_s, ft (pier)	_____	_____
y_s, ft (contraction)	_____	_____
Total scour, ft	_____	_____
Normal streambed elev.	_____	_____
Scour elevation	_____	_____

Is y_s or the total scour depth at the pier realistic?
Is the soil scourable?
What is the effect on pile stability?
Should riprap or other countermeasures be used?
What is the rating for SI&A Item 113?
Other comments?

Sediment Grade Scale, from "Stream Stability at Highway Structures", Hydraulic Engineering Circular No. 20, Federal Highway Administration, Second Edition, November 1995.

| SEDIMENT GRADE SCALE					
Size			*Approximate Sieve Mesh Openings (per inch)*		*Class*
Millimeters	Microns	Inches	Tyler	U.S. Standard	
4000-2000	---	180-160	---	---	Very Large Boulders
2000-1000	---	80-40	---	---	Large Boulders
1000-500	---	40-20	---	---	Medium Boulders
500-250	---	20-10	---	---	Small Boulders
250-130	---	10-5	---	---	Large Cobbles
130-64	---	5-2.5	---	---	Small Cobbles
64-32	---	2.5-1.3	---	---	Very Coarse Gravel
32-16	---	1.3-0.6	---	---	Coarse Gravel
16-8	---	0.6-0.3	2.5	---	Medium Gravel
8-4	---	0.3-0.16	5	5	Fine Gravel
4-2	---	0.16-0.08	9	10	Very Fine Gravel
2.00-1.00	2000-1000	---	16	18	Very Coarse Sand
1.00-0.50	1000-500	---	32	35	Coarse Sand
0.50-0.25	500-250	---	60	60	Medium Sand
0.25-0.125	250-125	---	115	120	Fine Sand

0.031-0.016	31-16	---			Medium Silt
0.016-0.008	16-8	---			Fine Silt
0.008-0.004	8-4	---			Very Fine Silt
0.004-0.0020	4-2	---			Coarse Clay
0.0020-0.0010	2-1	---			Medium Clay
0.0010-0.0005	1-0.5	---			Fine Clay
0.0005-0.0002	0.5-0.24	---			Very Fine Clay

Case 1 Contraction Scour, from Appendix H, "Evaluating Scour at Bridges", Hydraulic Engineering Circular No. 18, Federal Highway Administration, Second Edition, April 1993.

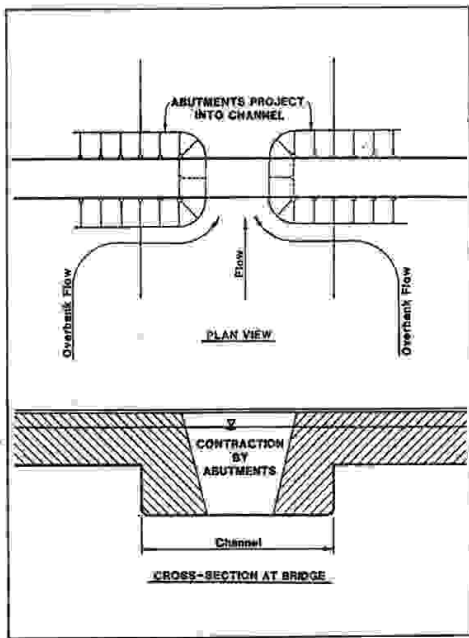

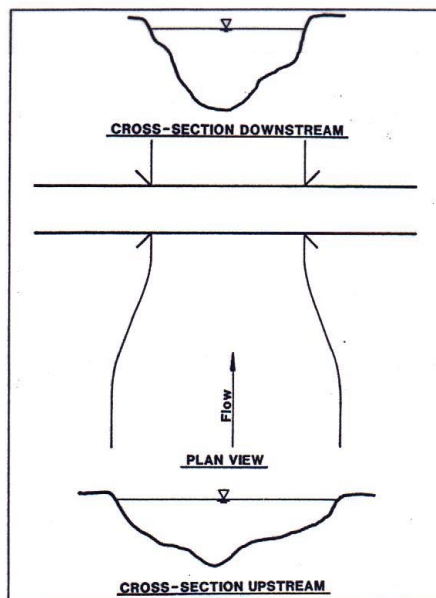

Case 1A: Abutments project into channel

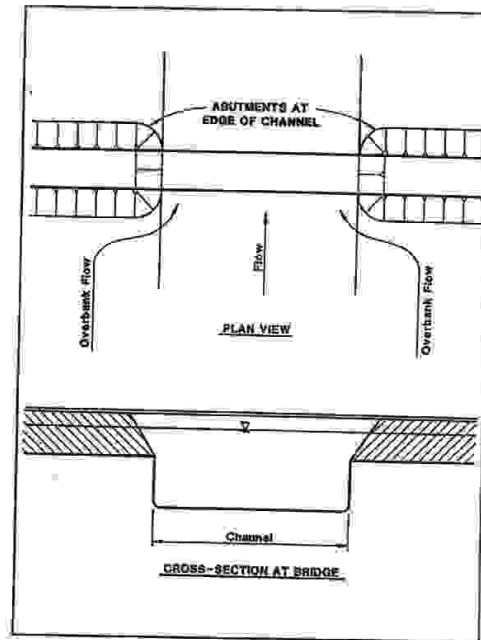

Case 1B: Abutments at edge of channel
Case 1C: Abutments set back from channel

Cases 2, 3 and 4 Contraction Scour, from Appendix H, "Evaluating Scour at Bridges", Hydraulic Engineering Circular No. 18, Federal Highway Administration, Second Edition, April 1993.
Case 2A: River narrows

Case 2B: Bridge abutments constrict flow

Case 3: Relief bridge over flood plain
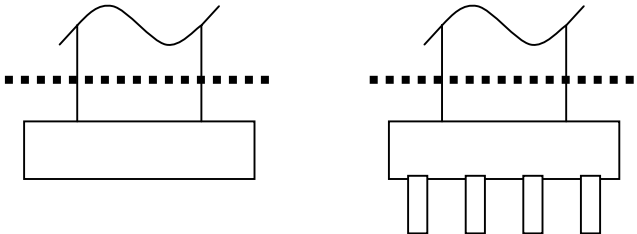

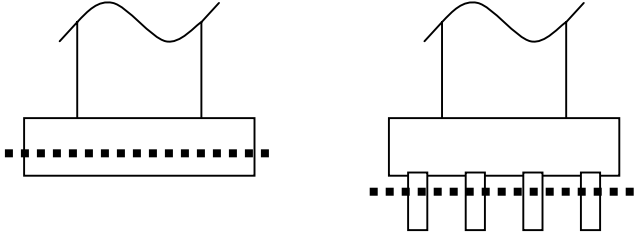

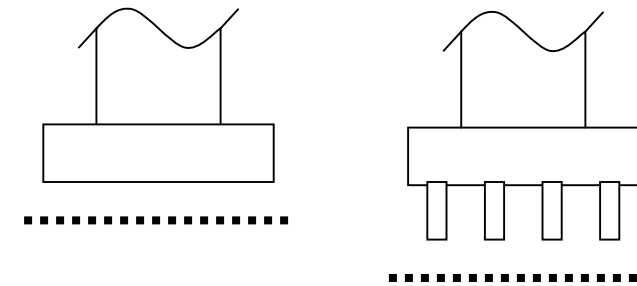

Case 4: Relief bridge over secondary stream

From "Recording and Coding Guide for the Structure Inventory and Appraisal of the Nation=s Bridges", Federal Highway Administration, December 1995.

ITEM 113--SCOUR CRITICAL BRIDGES

Use a single-digit code as indicated below to identify the current status of the bridge regarding its vulnerability to scour. Scour analyses shall be made by hydraulic/geotechnical/structural engineers. Details on conducting a scour analysis are included in the FHWA Technical Advisory 5140.23 titled, "Evaluating Scour at Bridges". Whenever a rating factor of 4 or below is determined for this item, the rating factor for "Item 60 – Substructure" may need to be revised to reflect the severity of actual scour and resultant damage to the bridge. A scour critical bridge is one with abutment or pier foundations which are rated as unstable due to (1) observed scour at the bridge site or (2) a scour potential as determined from a scour evaluation study.

Code	Description
N	Bridge not over waterway.
U	Bridge with "unknown" foundation that has not been evaluated for scour. Since risk cannot be determined, flag for monitoring during flood events and, if appropriate, closure.
T	Bridge over "tidal" waters….
9	Bridge foundations (including piles) on dry land well above floodwater elevations.
8	Bridge foundations determined to be stable for assessed or calculated scour conditions; calculated scour is above top of footing. (Example A)
7	Countermeasures have been installed to correct a previously existing problem with scour. Bridge is no longer scour critical
6	Scour calculation/evaluation has not been made. (Use only to describe cases where bridge has not yet been evaluated for scour potential.)
5	Bridge foundations determined to be stable for calculated scour conditions; scour within limits of footing or piles. (Example B)
4	Bridge foundations determined to be stable for calculated scour conditions; field review indicates action is required to protect exposed foundations from effects of additional erosion and corrosion.
3	Bridge is scour critical; bridge foundations determined to be unstable for calculated scour conditions: --Scour within limits of footing or piles. (Example B) --Scour below spread-footing base or pile tips. (Example C)
2	Bridge is scour critical; field review indicates that extensive scour has occurred at bridge foundations. Immediate action is required to provide scour countermeasures.
1	Bridge is scour critical; field review indicates that failure of piers/abutments is imminent. Bridge is closed to traffic.
0	Bridge is scour critical. Bridge has failed and is closed to traffic.

Example	Calculated Scour Depth		Action Needed
	Spread Footing (not founded in rock)	Pile Footing	
A. Above top of footing			None--indicate rating of 8 for this item
B. Within limits of footing or piles			Conduct foundation structural analysis
C. Below pile tips or spread footing base			Provide for monitoring and scour countermeasures as necessary.
